

DARWIN/XLZD: a future xenon observatory for dark matter and other rare interactions

Laura Baudis 

^aDepartment of Physics, University of Zurich, Winterthurerstr. 190, Zurich, 8057, Switzerland

Abstract

The DARWIN/XLZD experiment is a next-generation dark matter detector with a multi-ten-ton liquid xenon time projection chamber at its core. Its principal goal will be to explore the experimentally accessible parameter space for Weakly Interacting Massive Particles (WIMPs) in a wide mass-range, until interactions of astrophysical neutrinos will become an irreducible background. The prompt scintillation light and the charge signals induced by particle interactions in the liquid xenon target will be observed by VUV-sensitive, ultra-low background photosensors. Besides its excellent sensitivity to WIMPs with masses above ~ 5 GeV, such a detector with its large mass, low-energy threshold and ultra-low background level will also be sensitive to other rare interactions, and in particular also to bosonic dark matter candidates with masses at the keV-scale. We present the detector concept, discuss the main sources of backgrounds, the technological challenges and some of the ongoing detector design and R&D efforts, as well as the large-scale demonstrators. We end by discussing the sensitivity to particle dark matter interactions.

Keywords: dark matter, direct detection, liquid xenon time projection chambers, rare event searches

1. Introduction

There is a vast body of evidence for dark matter (DM) across many length scales in the Universe, but its fundamental nature remains a mystery. Cold dark matter is one of the foundations of the standard model of cosmology, Λ CDM, accounting for 26.4% of the critical density, or 84.4% of the total matter density (Aghanim et al., 2020). While DM candidates extend over a large range of masses and interaction cross sections, two classes of models stand out: Weakly Interacting Massive Particles (WIMPs) and axions, for these are theoretically well-motivated by open questions in particle physics (Workman et al., 2022).

Direct DM detection experiments search for rare scatters between a DM particle and an atomic nucleus or for interactions with electrons in various target materials. Operated deep underground to reduce background from cosmic rays, these experiments face two major challenges: the small energies, well below tens of keV and perhaps as low as a few meV, released in a collision and the ultra-low scattering rates. Because of the unknown DM interaction cross section, expected rates range from about 10 to much less than 1 event per ton of detector material and year, depending on the DM particle mass. This is an extraordinarily small rate, requiring a low energy threshold, an ultra-low background from radioactivity and a target mass as large as possible, to maximise the probability of a discovery.

2. Liquid Xenon Experiments

Experiments using liquefied xenon (LXe) as DM target have reached the highest sensitivity to WIMPs with masses above a few GeV, as shown in Figure 1. Owing to their low background rates and energy thresholds around 1 keV, LXe experiments are

also sensitive to other new types of particle interactions, as well as to low-energy astrophysical neutrinos. In fact, the latter will induce an irreducible background in the next-generation of detectors at the multi-ten-ton scale.

Figure 1: Exclusion limits (solid) on the spin-independent WIMP-nucleon cross section from a range of direct DM detection experiments, including dual-phase TPCs. Projections for LZ and XENONnT (dashed) and for DARWIN/XLZD (dashed-dotted) are also shown. The region where a distinction between a dark matter signal and astrophysical neutrinos will be challenging, albeit not impossible (O’Hare, 2021), is shown in blue.

Some advantages of xenon experiments are their large and homogeneous detector geometries with efficient self-shielding against external radiation, the fact that their targets are readily purified, as well as their sensitivity to both, spin-independent and spin-dependent WIMP interactions, given the presence of two isotopes with spin, ^{129}Xe (26.44%) and ^{131}Xe (21.18%), in natural xenon. The radioactive isotopes ^{124}Xe , ^{126}Xe , ^{134}Xe and ^{136}Xe have very long half-lives, and their second-order weak decay modes present interesting physics channels.

Xenon-based experiments employ dual-phase (liquid and

gas) TPCs, the working principle of which is shown schematically in Figure 2. An interaction within the active volume of a detector will create ionisation electrons and prompt scintillation photons. The prompt scintillation signal (S1) is detected with two arrays of photosensors, one in the liquid phase on the bottom and one in the gas phase at the top. The electrons drift in the pure liquid under the influence of an external electric field, are then accelerated by a stronger field and extracted into the vapour phase above the liquid, where they generate proportional scintillation, or electroluminescence. The delayed proportional scintillation signal (S2) is observed by the same photosensor arrays. The array immersed in the liquid collects the majority of the prompt signal, which is totally reflected at the liquid-gas interface. The ratio of the two signals is different for nuclear recoils (NR), such as from fast neutron interactions or hypothetical WIMPs and electronic recoils (ER) produced by β and γ -rays, or DM particles scattering off electrons. This provides the basis for background discrimination in dark matter detectors. Since electron diffusion in the ultra-pure liquid is small (albeit non-negligible), the proportional scintillation photons carry the $x - y$ information of the interaction site. With the z -information from the drift time measurement, the TPC yields a three-dimensional event localisation, enabling fiducial volume selections and differentiation between single- and multiple-scatters in the active volume (Baudis, 2023).

Figure 2: The operation principle of a dual-phase xenon TPC. A particle interaction in liquid xenon gives rise to a prompt scintillation signal (S1) and a delayed, amplified proportional scintillation signal (S2). The latter is caused by ionisation electrons, which are drifted in a homogeneous electric field (of a few 100 V/cm) and extracted into the gas phase above the liquid with a higher electric field, typically 10 kV/cm. The drift field is produced between the cathode at negative potential and a grounded gate grid in the liquid, while the extraction field is obtained by means of the anode placed above the gate in the gas phase. Both S1 and S2 signals are observed with photosensor arrays placed on the bottom and top of the TPC.

3. Backgrounds

The target masses of dual-phase xenon TPCs were gradually scaled up from a few kg to multi-tons, while the backgrounds were concomitantly reduced for each detector iteration. This

lead to the remarkable evolution of the sensitivity to WIMPs, as shown in Figure 3, which covers over three decades.

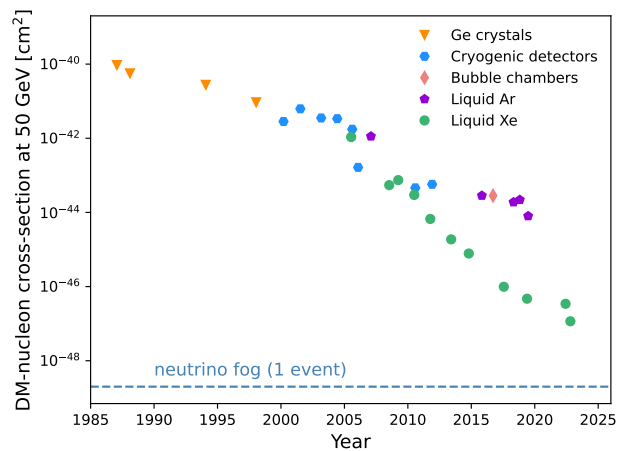

Figure 3: Evolution of the sensitivity to spin-independent WIMP-nucleon interactions for a 50 GeV WIMP, for various technologies, including dual-phase Xe-TPCs, with time. The so-called neutrino fog is shown as a horizontal dashed line. Note the logarithmic scale.

The present background goals are such that electronic and nuclear recoils rates are below the ones from irreducible astrophysical neutrino interactions. This requirement sets the goals for the intrinsic ^{222}Rn and ^{85}Kr concentrations: the background from the decay of these isotopes is to be below the solar pp-neutrino elastic scattering rate, as shown in Figure 4. This condition translates into $0.1\mu\text{Bq/kg}$ for ^{222}Rn and 0.1ppt for ^{85}Kr , assuming a $^{85}\text{Kr}/^{nat}\text{Kr}$ ratio of 2×10^{-11} . ^{nat}Kr concentrations of $< 50\text{ppq}$ were already achieved by cryogenic distillation (Aprile et al., 2022), while for ^{222}Rn a factor of about 10 reduction compared to the current value of $0.8\mu\text{Bq/kg}$ in XENONnT is needed for future detectors, see Figure 5. As an example, a ^{222}Rn concentration of $0.1\mu\text{Bq/kg}$ corresponds to less than one radon atom per 100 mol of xenon. The main background is due to ^{214}Bi β -decays which are not accompanied by an α -decay and thus cannot be tagged in the TPC.

The neutron-induced NR backgrounds must be below the rate from coherent elastic neutrino-nucleus scatters (CEvNs) from solar and atmospheric neutrinos. Muon-induced neutrons (cosmogenic) are suppressed by going deep underground and surrounding the experiment with a large water Cherenkov shield. Neutrons from (α, n) and fission reactions in detector components are reduced by severe material selection criteria in terms of radio-purity, and via dedicated neutron shields surrounding the cryostat (e.g., Gd-doped water or liquid scintillator). The neutron shields tag neutrons which might scatter once in the TPC and then escape from the inner detector. They also provide an *in situ* measurement of the neutron background close to the TPC.

The scattering of ^8B solar neutrinos can mimic WIMPs with masses around 5-6 GeV, while neutrinos from the atmosphere and diffuse supernova neutrinos can mimic a WIMP-signal for masses above 10 GeV. While these neutrinos will present irreducible backgrounds for the DM search, they can, on the other

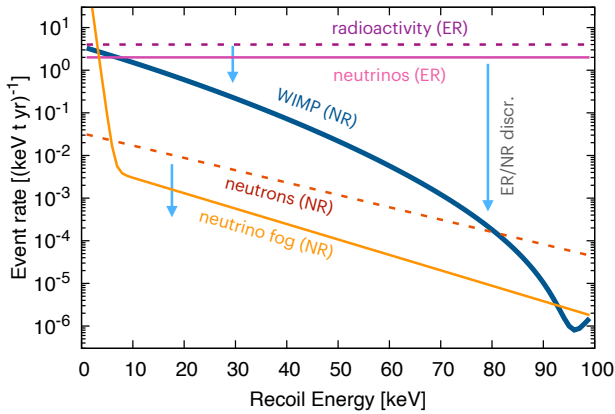

Figure 4: Schematic view of the main backgrounds in xenon TPCs, together with a hypothetical, WIMP-induced NR spectrum. The ER background rates, mainly from radioactivity (radon mixed with the xenon) is to be reduced below the irreducible background from elastic neutrino-electron scatters from solar neutrinos. The NR background rate from neutrons (radiogenic and cosmogenic) is to be reduced below the irreducible rate from coherent elastic neutrino-nucleus scatters (neutrino fog) from solar and atmospheric neutrinos. Finally ERs and NRs can be distinguished based on their S1 and S2 signals (ER/NR discrimination). Figure by Tina Pollmann.

hand, also be promoted from backgrounds to signals, allowing to address open questions in neutrino and solar physics (Baudis et al., 2014; Aalbers et al., 2020).

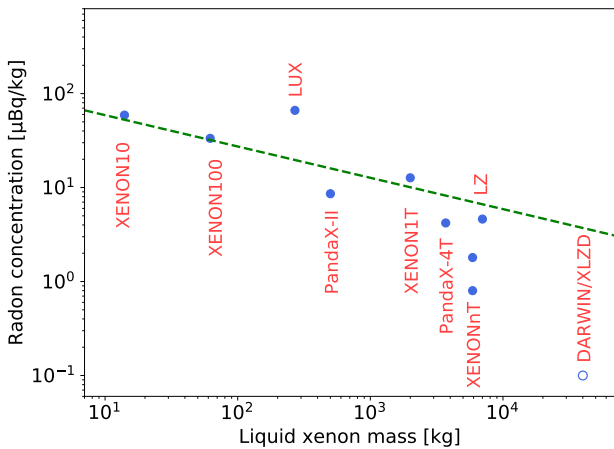

Figure 5: The evolution of ^{222}Rn concentration in two-phase Xe-TPCs (measured values, blue dots), together with the expected decrease from the surface-to-volume ratio (dashed line, $x^{-1/3}$). The goal for next-generation TPCs (open circle) is also shown.

4. Overview of past, current and future detectors

The first dual-phase Xe-TPCs that set competitive constraints on WIMP scatters off nuclei were those of the ZEPLIN and XENON programmes, in particular ZEPLIN-II and ZEPLIN-III at the Boulby Mine in the UK, and XENON10 at LNGS in Italy. These evolved into LUX and LUX-ZEPLIN at SURF, USA, and XENON100, XENON1T and XENONnT at LNGS. In parallel, PandaX-I and PandaX-II were constructed at the China

Experiment	Cross section [cm ²]	WIMP mass [GeV/c ²]
LUX-ZEPLIN	6.5×10^{-48}	30
PandaX-4T	3.8×10^{-47}	40
XENONnT	2.6×10^{-47}	28

Table 1: Minima of the upper limits on the spin-independent WIMP-nucleon cross sections from the first science runs of the three ongoing multi-tonne xenon experiments LUX-ZEPLIN (Aalbers et al., 2023b), PandaX-4T (Meng et al., 2021) and XENONnT (Aprile et al., 2023a).

Jinping Underground Laboratory (CJPL), followed by PandaX-4T. Starting with total masses at the few kilogram and later 100 kg scale, the detectors evolved and reached target masses at the tonne- and more recently multi-tonne scale. Concomitantly, the background levels in the most inner regions constantly decreased, with now unprecedented electronic recoil levels around 15 events/(t y keV) in the energy region below 100 keV.

The current generation of detectors employ several tons of LXe: LZ (Akerib et al., 2020), PandaX-4T (Meng et al., 2021) and XENONnT (Aprile et al., 2020) have total (target) LXe masses of 10 t (7 t), 5.6 (3.7 t) and 8.6 t (5.9 t), respectively. Their overall TPC design is rather similar, with cylindrical, PTFE enclosed target regions viewed by two arrays of 3-inch diameter Hamamatsu R11410 PMTs. The LUX-ZEPLIN and XENON programmes are reviewed by D. Akerib and E. Aprile, respectively, in this issues. All three experiments presented first results on WIMPs, as well as on other DM candidates, from their early science runs, and continue to acquire data towards their design exposures and sensitivities. No evidence for DM was found, the data being consistent with background-only hypotheses. The minima of the spin-independent WIMP-nucleon cross sections for the three ongoing experiments are shown in Table 1. The search for WIMP dark matter is ongoing, with a sensitivity goal around 1.5×10^{-48} cm² at 40-50 GeV/c² mass (Akerib et al., 2020; Aprile et al., 2020).

The next-generation projects are DARWIN/XLZD, described in more detail in the following sections, and PandaX-xT. DARWIN, first proposed around 2011 (Baudis, 2012a), would operate a TPC with 40 t of LXe in the active region (50 t in total) (Aalbers et al., 2016). In June 2021 the LZ, XENON and DARWIN collaborations signed an MoU and joined forces to form the XLZD consortium (Consortium, 2022), with the goal of constructing and operating the next-generation experiment together. The size and scope of the detector might be enlarged, compared to DARWIN, with a 3 m×3 m TPC containing 60 t of LXe (75 t in total). PandaX-xT is the next step in the PandaX programme at CJPL, with 43 t of LXe target in the TPC (47 t of LXe in total). Two arrays of Hamamatsu R12699 2-inch PMTs will view the Xe volume. Compared to the 3-inch tubes employed in current TPCs, these new sensors have the advantage of lower radioactivity, faster time response and the possibility of multi-anode readout, with four independent channels per unit. The inner cryostat vessel will be made of ultra-pure copper, and the space between the inner and outer vessel will contain an active veto. PandaX-xT aims for a 200 ty exposure for WIMPs, and, similar to DARWIN/XLZD, for a broad

science reach (Wang et al., 2023).

5. The DARWIN/XLZD Project

In its baseline design, shown in Figure 6, the DARWIN experiment features a cylindrical TPC, with 2.6 m diameter and 2.6 m height, placed in a low-background, double-walled titanium cryostat. The cryostat and its support structure is surrounded by active neutron and muon vetos. Two photosensor arrays with a total of 1910 3-inch PMTs are located at the top and bottom of the TPC, which is lined with high-reflectivity polytetrafluoroethylene (PTFE), surrounded by 92 copper field shaping rings (Aalbers et al., 2016). The larger mass of XLZD would imply a TPC with 3 m diameter and 3 m height, with a first phase employing a full-scale diameter but shallower TPC (with 40 t active mass), and possibly a final phase with an enlarged, taller TPC, to accommodate 80 t of active mass.

Figure 6: Schematic view of the DARWIN baseline design. The cylindrical TPC, enclosed by a double-walled titanium cryostat, is 2.6 m in diameter and height. Two arrays of 3-inch PMTs are located at the top and bottom of the TPC, which is lined with high-reflectivity PTFE and surrounded by 92 Cu field shaping rings (Aalbers et al., 2016).

Regardless of the exact final dimensions, a detector at the DARWIN/XLZD scale (2.6-3.0 m) poses several technological challenges. The stringent background goals regarding radon levels require cryogenic distillation with a high liquid xenon throughput (close to 1 t/hour) with efficient cooling power based on cryogenic heat pumps and radon-free heat exchangers. Cryogenic distillation alone is not sufficient: it must go hand in hand with selection of materials with low radon emanation rates and, in some cases, with new coating techniques to prevent radon emanation from cryostat surfaces. Other challenges related to the liquid target are the continuous purification for electronegative impurities and water, to maintain high charge and light yields, as well as new solutions for reliable xenon storage and recuperation at large scales. Liquid phase purification powered by a liquid xenon pump, as demonstrated in (Plante

et al., 2022), was employed to achieve an electron drift lifetime above 10 ms in about 8.6 t of xenon in XENONnT. Hence liquid phase purification will also be used for DARWIN, along with purification of the gaseous volume of the cryostat. The latter remains crucially important to extract radon and other impurities from detector parts with elevated impurity concentrations, such as, e.g., pipes containing cabling.

Regarding the detector design, electrodes with large diameters, high transparency, minimal sagging and low spurious electron emission, as well as high-voltage feed-throughs that can safely deliver 50 kV or more to the cathode must be developed. The LZ collaboration successfully built custom-woven wire-mesh grids with 1.5 m diameter, produced with an in-house built loom to weave the wire meshes (Stifter, 2020). However, the new electrodes require a scale-up of a factor of two in linear dimensions compared to existing electrodes in XENONnT and LZ. To this end, several types of large-scale electrodes must be produced and the performance of prototypes must be assessed in test platforms above and below ground. The latter in particular would also allow to probe spurious charge and light emissions, which can contribute to the combinatorial background in the TPC, and affect the backgrounds at low energies.

The baseline TPC design will employ two arrays of low-radioactivity, 3-inch diameter PMTs (Hamamatsu R11410-21/22), as developed by Hamamatsu with the XENON and LZ collaborations over many years for operation in liquid xenon, and optimised for low radioactivity, low spurious light emission and vacuum tightness at low temperatures (Baudis et al., 2013; Barrow et al., 2017; Antochi et al., 2021). These PMTs have a low dark count rate (~ 0.02 Hz/mm²) and a high quantum efficiency ($\sim 34\%$) to the xenon 175 nm scintillation light. The arrangement of the tubes in the arrays will optimise the light collection efficiency and the $x - y$ -position reconstruction using the S2-signal. While specific activities of < 13.3 mBq/PMT and < 0.6 mBq/PMT, for ²³⁸U and ²³²Th were achieved, respectively, in the current generation of tubes (Aprile et al., 2015), further optimisation of the employed materials will be necessary to reach the background goals. Finally the cryostat design will be optimised to ensure stability, while reducing as much as possible the amount of material, and thus gamma and neutron emitters in proximity to the TPC.

Although the baseline detector design is well-established, and PMTs are by now a proven technology for cryogenic operation, R&D for new type of photosensors, which could potentially replace the 3-inch tubes in future upgrades of the detector, as well as for new TPC designs, is ongoing. The studied sensors in the DARWIN collaboration include VUV-sensitive silicon photomultipliers (Sakamoto et al., 2023; Peres, 2023; Baudis et al., 2020, 2018) and digital SiPMs, the 2-inch \times 2-inch flat panel PMTs (Hamamatsu R12699), hybrid photosensors (D'Andrea et al., 2022), as well as bubble-assisted liquid hole multipliers (Breskin, 2022).

6. Large-scale demonstrators

To address some of the challenges related to the construction and operation of such a next-generation Xe-TPC, several large-

scale demonstrators have been built and are in operation. The Xenoscope facility in Zurich includes a 2.6 m tall TPC (Baudis et al., 2021, 2023), while the Pancake facility in Freiburg allows to deploy a shallow, 2.6 diameter TPC. The facilities, which use about 400 kg of liquid xenon in their cryostats, are shown in Figure 7.

Figure 7: Pictures of the large-scale DARWIN R&D facilities Xenoscope, in Zurich (top), and Pancake, in Freiburg (bottom). Xenoscope (Baudis et al., 2021, 2023) will operate a 2.6 m tall TPC inside the 3.5 m tall cryostat, while Pancake will test 2.6 diameter electrodes as well as a 2.6 diameter TPC.

The main aim of Xenoscope is to demonstrate electron drift over 2.6 m, to measure longitudinal and transversal electron cloud diffusion for different electric drift fields, as well as light attenuation in liquid xenon over these large distances. Figure 8 shows the 2.6 m tall TPC with its top SiPM array. The main aim of Pancake is to test electrodes with large (>2.5 m) diameters. Both facilities are available as R&D platforms to the collaboration. A new facility, LowRad, to demonstrate large-scale cryogenic distillation is under construction in Münster. Apart from these large-scale demonstrators, smaller projects to study new types of inner detectors and to test new photosensors are ongoing. The new detector designs include single-phase TPCs with S2 amplification in the liquid, liquid xenon proportional counters (Qi et al., 2023), and so-called hermetic or sealed TPCs (Sato et al., 2020; Wei et al., 2021; Dierle et al., 2023). For the latter, the inner liquid xenon volume is mechanically isolated from the rest of the detector, which contains a large

fraction of radon-emanating surfaces, to prevent radon diffusion into the sensitive xenon volume.

Figure 8: Picture of the 2.6 m tall TPC installed in Xenoscope (top). Visible are the Cu field shaping rings, as well as the Torlon support pillars. At the top of the TPC, a SiPM array (bottom) records the S2 signals. It is composed of twelve tiles of 24×24 mm² total area, containing 192 individual 6×6 mm² SiPM units (Peres, 2023).

7. Sensitivity to Dark Matter

With its large target mass and ultra-low background rates, the next-generation xenon detector will be a true observatory in astroparticle physics. It will not only search for dark matter, but also detect low-energy astrophysical neutrinos, search for neutrinoless double beta decay in ^{136}Xe without the need of target enrichment, look for solar axions, as well as for other rare interactions. The science potential of a large, dual-phase xenon detector is detailed in (Aalbers et al., 2023a), a white paper signed by 600 authors. Here we briefly discuss the sensitivity to dark matter.

The primary science goal of DARWIN/XLZD is to discover WIMPs, or, should a first signal appear in current-generation detectors, to constrain their mass and cross section with higher sensitivity. As an example, Figure 9 shows the capability of a liquid xenon detector to reconstruct the DM mass and cross section, for three different masses (20 GeV, 100 GeV and 250 GeV) and a SI WIMP-nucleon cross section of 1×10^{-47} cm². The $1\text{-}\sigma$ and $2\text{-}\sigma$ credible regions are obtained after marginalising

the posterior probability distribution over astrophysical parameters: galactic escape velocity $v_{\text{esc}} = (544 \pm 40) \text{ km/s}$, circular velocity $v_0 = (220 \pm 20) \text{ km/s}$ and local DM density $\rho_0 = (0.3 \pm 0.1) \text{ GeV/cm}^3$ (Newstead et al., 2013).

Figure 9: Capability of a liquid xenon detector such as DARWIN/XLZD to reconstruct the DM mass and cross section, for three different masses, 20 GeV, 100 GeV and 500 GeV and a SI WIMP-nucleon cross section of $1 \times 10^{-47} \text{ cm}^2$. Figure from (Newstead et al., 2013).

With an exposure of 200 ty, the next-generation detector will close the gap to the so-called neutrino fog, when astrophysical neutrinos will start to limit the sensitivity to WIMPs. The larger mass of XLZD, compared to the baseline DARWIN design, would allow for a $3\text{-}\sigma$ WIMP discovery at a SI cross section of $3 \times 10^{-49} \text{ cm}^2$ at $40 \text{ GeV}/c^2$ mass. This is illustrated in Figure 10, which also shows the systematic limit imposed by coherent elastic neutrino nucleus scatters from solar and atmospheric neutrinos. At a given contour n , an increase in exposure by at least a factor of 10^n is required to probe a 10 times lower cross section (O’Hare, 2021).

Figure 10: The $3\text{-}\sigma$ WIMP discovery sensitivity of DARWIN/XLZD at a SI cross section of $3 \times 10^{-49} \text{ cm}^2$ at $40 \text{ GeV}/c^2$ for two different exposures, 200 ty and 1000 ty, as well as the 90% exclusion sensitivity for an exposure of 200 ty. The systematic limit imposed by coherent elastic neutrino nucleus scatters from solar and atmospheric neutrinos is also shown. At a given contour n , an increase in exposure by at least a factor of 10^n is required to probe a 10 times lower cross section (O’Hare, 2021). Figure by Ciaran O’Hare.

As already demonstrated by previous and the current generation of detectors, xenon TPCs can also search for non-WIMP

dark matter candidates. These include searches for keV-scale axion-like-particles (ALPs) and dark photons via absorption in LXe, for DM candidates in the mass range $\sim 50 \text{ MeV}$ - 10 GeV from a hidden sector, via DM electron scattering, and even for Planck-scale dark matter (Aprile et al., 2023b). DARWIN/XLZD, with a 40-60 t LXe target, and a background dominated by neutrinos, will vastly improve upon current constraints.

8. Summary and conclusions

After decades of intense research, the fundamental nature of dark matter in the Universe remains an enigma. In the race to discover DM particles, dual-phase Xe-TPCs remain at the forefront. Developed in the early twenty-first century primarily to search for dark matter in the form of WIMPs, they soon surpassed other technologies in terms of their sensitivity to WIMP-nucleon interactions over a large range of WIMP masses (Baudis, 2012b). Almost twenty years later, detectors using several tonnes of liquid xenon can observe signals down to a few quanta (photons and electrons) with unprecedented low background rates, approaching the irreducible background from astrophysical neutrinos. While the current generation of detectors continue to acquire data in different deep underground laboratories, a next-generation experiments at the multi-ten-ton scale, DARWIN/XLZD, is in planning. Although by now an established technology, the scaling up of the Xe-TPCs from diameters and heights of 1.5 m to about twice these dimensions poses several technological challenges. To address these, large-scale R&D projects are ongoing, with two full-scale demonstrators in operation. Several smaller scale detectors explore alternative designs and photosensors, which, albeit not part of the baseline design, could be potentially employed in future upgrades of the detector. With foreseen first data in the early 2030s, DARWIN/XLZD might discover dark matter particles, and thus solve a problem which is almost a century old. At the same time, it will break new grounds in other areas of astroparticle physics, in particular in neutrino physics and very rare nuclear transitions.
